# Foreword

The first set of population projections for Hong Kong was made on the basis of information from the 1961 Census and birth and death statistics and migration data then available. Since 1961, new projections have been made every 5 years after each population census.

This report, which is the fourth in the series, gives the projections by age and sex, based on the mid-1976 population estimates from the 1976 By-census (which was taken on 2 August 1976); it also gives a comprehensive description of the method of projection and the detailed assumptions employed. The 20-years spread follows the pattern of the previous set; it represents a balance between the requirements of users and the diminishing reliability of assumptions with time.

Compared with previous series, the new projections have the advantage of being based on more up-to-date birth and death statistics and more (if still incomplete) information on migration, including the age and sex structure of migrants. But, however firm the present base may be, the future uncertainty remains. This is particularly so in relation to migration; it is also so in the case of fertility which has become low to a point that gives rise to particular difficulties in foreseeing its future.

The report is divided into two parts. Part I gives a summary of the method and also the detailed results. Part II contains a more detailed exposition of past history and the assumptions and methods of computation used. At the end is a list of definitions of terms used in this report.

# **Part I**

## **General Account of Population Projections**

### **The purpose of the projection**

The main purpose of population projection is to provide an estimate of the total future population of Hong Kong and its composition by age and sex as a common framework for use in forward planning generally, principally in development fields in the public sector such as housing, education, transport, medical and social services.

The population projections previously available were prepared in 1972. These were based on the age and sex distribution derived from the 1971 Census and a particular set of assumptions about the future number of births, deaths and migrants, which drew on past experience and incorporated the information then available. Some changes in these demographic factors have occurred since the last projections were made and new information on the age and sex distribution is available from the 1976 By-census. New population projections for the period from 1976 to 1996, therefore, have been made on revised assumptions concerning future fertility, mortality, immigration and emigration.

### **The method of projection**

The standard method of population projection is by components. This method involves the specification of the population elements by sex and by age intervals and the separate projection of each component of population change (i.e. fertility, mortality and migration).

The first step in projecting is to select a base population year. These projections use the year 1976, since the 1976 By-census has provided the latest information on the size and age distribution of the population. The By-census population has first been adjusted for mis-statements of age, and then brought back to mid-year 1976 (the By-census reference date was 2 August 1976).

The projections of the population and its composition from the base year are then worked out year by year, based on projections of mortality and fertility and assumptions as regards migration.

First, projected survival ratios\* by sex and age are applied to the population at the beginning of a projection year, to derive the surviving population at the end of that year. Then the fertility factor is introduced; projected age-specific fertility rates† are applied to the average number of women in each of the child-bearing ages 15–49 to obtain the number of births in the year, which are then subject to specific survival ratios. Finally, the migration element is brought in; the assumed net balance of migration is added to/subtracted from the surviving population by sex and age at the end of the year. This three-fold process is repeated for each year of the overall projection period, giving for each year the projected population by age and sex.

### **Assumptions**

The projection method described above requires assumptions as to the future trends in the three components of fertility, mortality and migration. Implicit in these assumptions so far as the present exercise is concerned is the principle of continuity: that is to say that any changes in the future can be seen to be an extension of what has been happening in the past. Thus, a historical analysis is required to determine past trends, these provide the basis for the assumptions which are informed by present experience, subjective judgment and, where appropriate, experience from elsewhere.

Three different sets of assumptions are used, producing three projections – high, medium and low. These assumptions are set out in Appendix I. In pages 47 to 63 in Part II to this report may be found the background historical analysis and a fuller description of the assumptions.

Any projection is only as good as the assumptions on which it is based. The assumptions used here are made at a particular moment of time, on the basis of the statistical and other evidence available at the time. There is a large arbitrary element in the migration assumptions, in particular. The fertility assumptions are the most important for overall population size in the longer term. However, although it is unlikely that fertility would change abruptly over a short span of time, there must remain many uncertainties about trends in the longer term, bearing in mind that what one is attempting to do is to foresee the aggregate effect of the behaviour of many individuals in changing circumstances. This is particularly so when fertility becomes as low as it has in Hong Kong. In all this, therefore, there is inevitably a considerable element of subjective judgement.

### **The results of the projection**

There are three projections: high, medium and low. The high and low projections represent outer limits within which, saving some exceptional circumstances, the future population may confidently be expected to lie. The medium projection is based on the set of assumptions which at this time seem the most appropriate in the light of present trends and conditions, and is that which it would be reasonable to use as providing the most likely indication of the trend over the next 20 years.

The projections at one year intervals and by quinquennial age groups for the period 1977–96 are given in Appendix 2. The population pyramids for the years 1976, 1981, 1986, 1991 and 1996 (derived from the medium projection) are given in Appendix 3.

\*Survival ratio – the proportion of survivors in a cohort (which is a group of persons all born during the same year being analysed as a unit through their lifetime) at any particular age, derived from the specific life table based on the assumed schedule of death rates.

†Age-specific fertility rate – the ratio of the number of live births occurring to mothers in each child-bearing age group during a calendar year to the total female population in that age group at the middle of that year.

# Appendix I

## SUMMARY OF FERTILITY, MORTALITY AND MIGRATION ASSUMPTIONS

### Fertility assumptions

The projection of fertility trends involves the projection of age-specific birth rates by birth order. The birth rate for each birth order was projected based on past trends; the rate of increase or decrease derived from comparing the projected birth rate with that for the base year 1976 was assumed to be the same for each age group of mothers. The age-specific birth rates by birth order for each future year were projected by applying this rate of increase or decrease to the base year age-specific birth rates for each birth order. The projected age-specific fertility rates were derived from summing the projected age-specific birth rates over all birth orders.

#### *Projected changes in birth rate by birth order*

<i>High projection</i> 1976–1996	<i>1st order</i> Increasing along a log-linear trend fitted on the basis of past data	<i>2nd order</i> Remaining unchanged at the 1976 level	<i>3rd and higher order</i> Decreasing along a log-linear trend fitted on the basis of past data until reaching a prescribed low level
<i>Medium projection</i> 1976–1983	Remaining unchanged at the 1976 level	Same as above	Same as above
1983–1996	Increasing along a log-linear trend fitted on the basis of past data	Same as above	Same as above
<i>Low projection</i> 1976–1983	Remaining unchanged at the 1976 level	Decreasing along a log-linear trend fitted on the basis of past data	Decreasing at an average rate observed in 1975–76 until reaching a prescribed low level
1983–1996	Increasing along a log-linear trend fitted on the basis of past data	Remaining unchanged at the 1983 level	Same as above

### Mortality assumptions

The projection of mortality trends involves the projection of age-specific death rates for males and females. The standardized death rate (i.e. discounting the sex-age structure of the population) for each cause group was projected based on past trends. An index of increase or decrease was derived from comparing the projected death rate with that for the base period 1972–76. The index was disaggregated by age with reference to assumed age differentials in the mortality increase or decrease. The age-cause-specific death rates for each future year were projected by applying this index to the corresponding age-cause-specific death rates for the base period. The projected age-specific death rates for each sex were derived from summing the projected age-cause-specific death rates over all cause groups.

*High projection:* 5% lower than the projected sex-age-specific death rates used in the medium projection.

*Medium projection:* The projected sex-age-specific death rates as described above.

*Low projection:* 5% higher than the projected sex-age-specific death rates used in the medium projection.

### Migration assumptions

The assumptions about future migration were made separately for each component of migration. The sex and age structure of each of these migration components was assumed to be in line with the average distribution as observed in the past.

#### *Projected net balance of migration by component*

<i>Component</i>	<i>High projection</i>	<i>Medium projection</i>	<i>Low projection</i>
Emigrants	–20,000	–30,000	–35,000
Legal immigrants from China	26,000	22,000	18,000
Legal immigrants from other countries	7,000	7,000	7,000
Illegal immigrants (including overstayers)	15,000	13,000	10,000
Net balance of migration	28,000	12,000	nil

## FERTILITY TRENDS

### 1 Trends in birth rates

Hong Kong had a high birth rate in the pre-war and early post-war periods. Even in the late 1950's, the crude birth rate remained between 35 and 40 per thousand population. The decline in the birth rate only became apparent in the early 1960's. The crude birth rate dropped steadily from 35 per thousand in 1961 to 20 per thousand in 1970. The rate remained stable at the level of about 19.5 per thousand between 1971 and 1974 but in 1975, resumed its declining trend. The figure for 1976 was 17.7.

**Table 1.1 Crude birth rates, 1961–1976**

Year	Number of live births	Estimated mid-year population	Crude birth rate‡
1961	110,884*	3,168,100	35.0
1962	112,503*	3,305,200	34.0
1963	114,550*	3,420,900	33.5
1964	107,625*	3,504,600	30.7
1965	101,110*	3,597,900	28.1
1966	91,832*	3,629,900	25.3
1967	88,215*	3,722,800	23.7
1968	82,685*	3,802,700	21.7
1969	82,482†	3,863,900	21.3
1970	79,132†	3,959,000	20.0
1971	79,789†	4,045,300	19.7
1972	80,344†	4,115,700§	19.5
1973	82,252†	4,212,600§	19.5
1974	83,581†	4,319,600§	19.3
1975	79,790†	4,395,800§	18.2
1976	78,486†	4,443,800§	17.7

\*Figures based on registration of births with an adjustment for under-registration.

†Figures based on actual number of births delivered in hospitals, maternity homes and other institutions and registration of self-delivered births with slight adjustment for late-registration of self-delivered births.

‡Number of births per 1,000 population.

§Revised population estimates based on results of 1976 By-census.

### 2 Trends in fertility by age

The crude birth rate is calculated by relating the number of live births in a year to the average size of the population during the year. It can provide a simple and broad guide to the longer term trends. However, it cannot accurately reflect changes in fertility over time since it is based on the population at large, male and female, and even amongst the female population at risk (taken to be those in the fertile age group 15–49) is affected by changes in the age structure and such factors as age of marriage.

Age-specific fertility rates are a better measure of fertility because they are not affected by the age structure of the female population. Table 2.1 below shows the age-specific fertility rates for Hong Kong for the years 1969–1976 (the starting year of this and subsequent tables is dictated by limitations in the availability of information).

**Table 2.1 Age-specific fertility rates\*, 1969–1976**

Age group	Births per 1,000 female population							
	1969	1970	1971	1972†	1973†	1974†	1975†	1976†
15–19	17.4	18.1	17.0	17.4	17.9	18.8	17.8	17.4
20–24	172.1	155.3	145.0	139.3	132.5	133.3	121.5	109.7
25–29	242.8	233.4	243.0	248.0	243.3	219.2	198.6	192.1
30–34	178.2	168.8	162.2	145.8	141.8	137.4	126.0	119.6
35–39	92.8	87.1	83.3	77.4	72.4	65.7	54.5	48.9
40–44	37.4	31.0	28.4	25.8	23.5	21.1	18.3	14.6
45–49	5.9	4.4	3.6	3.2	3.2	2.5	2.4	1.5
Net reproduction rate (NRR)‡	1.779	1.655	1.625	1.552	1.497	1.415	1.255	1.185

\*Age-specific fertility rate is the ratio of the number of live births occurring to mothers in a child-bearing age group during a calendar year to the total female population in that age group at the middle of that year.

†Revised rates based on revised population estimates after 1976 By-census.

‡See page 48 for discussion of the concept of NRR.

It can be seen from Table 2.1 that the birth rates for almost all the fertile age groups declined steadily over the past 8 years. For the age groups 30 and over, the higher the age group the faster the rate of decrease. In the age group 25–29, there was a slight increase in the rate over the period 1970–72, but from 1973 onwards its birth rate also declined. Although the rate of decrease for this age group was comparatively less significant than that for the older age groups, because it is the most fertile age group the decline actually contributed appreciably to the overall fertility decline. To summarise, this rather uneven pattern of fertility decline was to a large extent associated with a marked decline in the number of high order births over this period.

**Table 2.2 Percentage distribution of live births by birth order, 1969–1976**

Year	1st order	2nd order	3rd order	4th order	5th order and above
1969	25.2	21.2	15.6	12.1	25.9
1970	26.5	22.3	16.1	11.9	23.2
1971	26.5	23.5	16.8	11.8	21.4
1972	31.7	22.7	16.5	10.6	18.5
1973	32.9	24.9	16.2	10.2	15.8
1974	37.6	25.8	15.2	8.8	12.6
1975	39.8	26.8	15.0	8.0	10.4
1976	38.9	30.6	15.1	7.3	8.1

Table 2.2 shows that, in each year during the period 1969–71, a substantial proportion (more than 20%) of the total live births were of a fifth child and above. This proportion dropped considerably in recent years and was only 8% in 1976. Broadly, the pattern reflected a general preference among women of younger ages for a small family; such a tendency would have a significant impact on the future age-specific fertility rates.

In the absence of the relevant data on births of, say,  $(x+1)$ <sup>th</sup> order relating to the total number of women who have born  $x$  number of children, it is not possible to compute the age-parity-specific\* fertility rates. However, a simple breakdown of the age-specific fertility rates by birth order can provide an indication of the effect of the general decline in high order births on the differential declines in fertility among different age groups.

\*Parity means the number of births to a mother.

**Table 2.3 Age-specific birth rates by birth order, 1970 and 1976\***

*Births per 1,000 female population*

Age group	1st order		2nd order		3rd order		4th order		5th order and above	
	1970	1976	1970	1976	1970	1976	1970	1976	1970	1976
15–19	13.6	13.9	4.0	3.2	0.5	0.3	—	—	—	—
20–24	76.7	63.5	50.0	35.2	21.3	9.0	6.0	1.7	1.3	0.3
25–29	54.8	66.8	64.5	69.5	54.6	35.4	35.7	14.5	23.8	5.9
30–34	14.4	16.6	27.2	31.8	31.7	29.9	33.8	20.2	61.7	21.1
35–39	3.3	3.9	6.6	8.0	9.7	8.5	12.8	8.1	54.7	20.4
40–44	0.6	0.6	1.2	1.2	2.2	1.5	2.7	1.7	24.3	9.6
45–49	0.1	0.1	0.2	0.1	0.3	0.1	0.5	0.1	3.3	1.1

\*Revised rates based on revised population estimates after 1976 By-census.

The third and higher order birth rates for all child-bearing age groups recorded a substantial decline during the period 1970–76, the higher the birth order the larger the decline. For each birth order rate, the rate of decrease was higher for the age groups under 30. The pattern of change, however, was somewhat different for the first and second order birth rates. There was a general increase in the rates for the age groups 25–39, but a moderate decrease for the young age groups 15–24.

### 3 The concept of population replacement

Before proceeding to the projection of fertility trends, it is necessary to explain briefly the concept of the net reproduction rate (NRR).

The NRR may be defined as the total number of female children that would be born per woman to a cohort of women as they pass through the reproductive ages 15–49, allowing for mortality of some of the women up to and during this period, according to constant fertility and mortality conditions. Thus, an NRR of 1 means that each woman during her child-bearing period would produce an average of one girl, who may be said to 'replace' her in the population. The population would then have a propensity to remain stationary. If the NRR remains at this level for a sufficiently long period of time (40 to 50 years), and provided that the net balance of migration is nil, the population would eventually become stationary. On the other hand, when the NRR is below unity, the population would have a propensity to diminish. It should be noted, however, that the NRR measures a hypothetical situation when the population is continuously subject to particular fertility conditions. If the schedule of age-specific fertility rates changes, the NRR also changes. In practice, it has been found that, after the NRR has reached a level of 1, it tends to fluctuate.

### 4 Method of fertility projection

The method of projecting fertility used in the present exercise consists of the projection of the birth rates by birth order for each child-bearing age. These detailed projections are informed by subjective judgments as to the likely future trend of NRR based on *inter alia* experience in developed countries which experienced rapid fertility decline in the past and whose NRRs are now at or below unity. Based on the projected age-specific fertility rates, the NRR for each year throughout the projection period is then computed. If the NRR so computed deviates significantly from this trend, the assumptions concerning future age-specific birth rates by birth order would be re-formulated and the process repeated until the resultant NRR approximately matches the pattern.

## 5 Future fertility trends

The NRR has been falling steadily over the past 8 years. If the present trend in the age-specific fertility rates continues in the future, it appears that the NRR would reach a level of 1 in the early 1980's. Since individual behaviour patterns only change slowly, it is unlikely that the NRR would remain immediately at the level of 1 and not fall below 1. On the other hand, it is unlikely that the NRR would stay forever below unity. Based on past trends of fertility decline in other low-fertility countries and on an appreciation of the position in Hong Kong, the judgment is that it would gradually rise back to 1 after a certain period of time, and then fluctuate about this level.

Experience over the past 8 years indicates that the high order birth rates were on a steadily declining trend. For the purposes of the projection, it is assumed that the present trend in the third and higher order birth rates would continue over the entire projection period and that the first and second order birth rates would increase, decrease or remain unchanged (as the case may be), from one period to another, so that the NRR derived from the projected age-specific fertility rates would approximately follow the general pattern thought likely to emerge.

*High projection* – The first order birth rate is assumed to increase along past trends (1970–76); the second order birth rate is assumed to remain unchanged at the 1976 level throughout the projection period. The third and higher order birth rates are assumed to decline along past trends (1970–76) until each reaches a prospective low limit which is subjectively fixed, based on the experience of other low-fertility countries. This will cause the NRR to drop to a level of 1 in 1983, which will continue to decline until it reaches 0.98 around 1986/1987 when the increase in the first order birth rate just balances the decline in the third and higher order birth rates. From then onwards, the NRR will increase slowly and finally reach 1 again in 1992.

*Medium projection* – The first order birth rate is assumed to remain unchanged at the 1976 level until 1983, and then to start increasing gradually. The second order birth rate is assumed to remain unchanged at the 1976 level throughout the projection period. The third and higher order birth rates are assumed to decline along past trends (1970–76) until each reaches a prospective low limit. Under these assumptions, the NRR will fall steadily to a level of 1 in 1981, and will continue to decline until it reaches 0.94 around 1987. From 1988 onwards, the NRR will increase slowly and will be back to 1 again in 1998.

*Low projection* – The first order birth rate is assumed to remain unchanged at the 1976 level until 1983, and then to start increasing gradually. The second order birth rate is assumed to decline along past trends (1970–76) until 1983, and then to remain unchanged over the rest of the projection period. The third and higher order rates are assumed to decline, following the more rapid rate of decrease in the past two years until each reaches a prospective low limit. Under these assumptions, the NRR will fall to a level of 1 in 1979 and will continue to decline until it reaches 0.89 around 1985. From then onwards, the NRR will increase steadily and eventually reach 1 again in the early 2000's.

## 6 Projected age-specific fertility rates

The projected change in the birth rate for each birth order is assumed to apply equally to all child-bearing age groups. Using the 1976 data as the base line, the projected age-specific birth rates by birth order for each successive future year can be calculated by adjusting the initial age-specific birth rates for each birth order by the projected rate of increase or decrease in that particular birth order rate for the respective future year compared with 1976. After repeating this process for all birth orders, the projected age-specific fertility rates can be arrived at by summing the projected age-specific birth rates over all birth orders. Table 6.1 shows the projected age-specific fertility rates for the years 1976, 1981, 1986, 1991 and 1996 for each of the three projections. A graphical illustration of the change in the pattern of fertility over the projection period is given in Chart B1.

## MORTALITY TRENDS

### 1 Trends in death rates

The level of mortality in Hong Kong was very high up to the outbreak of the Second World War; the crude death rate varied between 26 and 37 per thousand population. A major decline in mortality became apparent after the War. The rate was 10.2 in 1951 and 6.1 in 1961, a drop of 40% in a single decade. Thereafter decline was more gradual. Since 1964, the rate has recorded little significant change and has fluctuated about the level of 5 per thousand.

**Table 1.1 Crude death rates, 1961–1976**

<i>Year</i>	<i>Number of deaths</i>	<i>Estimated mid-year population</i>	<i>Crude death rate</i> ‡
1961	19,325*	3,168,100	6.1
1962	20,933*	3,305,200	6.3
1963	20,340*	3,420,900	5.9
1964	18,657*	3,504,600	5.3
1965	18,150*	3,597,900	5.0
1966	19,261*	3,629,900	5.3
1967	20,234*	3,722,800	5.4
1968	19,444*	3,802,700	5.1
1969	19,256*	3,863,900	5.0
1970	19,996*	3,959,000	5.1
1971	20,374†	4,045,300	5.0
1972	21,397†	4,115,700§	5.2
1973	21,251†	4,212,600§	5.0
1974	21,879†	4,319,600§	5.1
1975	21,597†	4,395,800§	4.9
1976	22,692†	4,443,800§	5.1

\*Figures based on registration of deaths with an adjustment for under-registration.

†Figures based on actual number of deaths occurred.

‡Number of deaths per 1,000 population.

§Revised population estimates based on results of 1976 By-census.

Changes in the crude death rate as shown in Table 1.1, however, do not accurately reflect changes in mortality over time. There are considerable differences in the risk of death at various ages and between sexes; changes in the age and sex structure of the population, therefore, affect the crude death rate. In order to show the trends in mortality during the period 1961–76, it is necessary to standardize the death rate based on the age and sex structure in a specific year. For easy comparison between different periods, the standardized death rates for the bench-mark years of 1966, 1971 and 1976 have been computed based on the sex-age distributions of 1961, 1966 and 1971 respectively.

**Table 1.2(a) Crude death rates and standardized death rates, 1961, 1966, 1971 and 1976**

<i>Year</i>	<i>Crude death rate</i>	<i>Standardized death rate</i>
1961	6.07	—
1966	5.32	4.91
1971	5.06	4.42
1976	5.11	4.52

**Table 1.2(b) Decline in crude death rates by component, 1961, 1966, 1971 and 1976**

<i>Period</i>	<i>% decline in crude death rate</i>	<i>% attributable to changes in sex-age structure</i>	<i>% attributable to decline in mortality</i>
1961–66	–12.4	+ 6.7	–19.1
1966–71	– 4.9	+12.0	–16.9
1971–76	+ 1.0	+11.7	–10.7

From the above, it can be seen that there was a continuous decline in mortality over the past 16 years, although the rate of decrease in the period 1971–76 was somewhat slower.

### 2 Differential mortality by age and sex

Mortality differs significantly between ages; the death rate starts at a high level in the first year of life, falls to a minimum near age 11, then moves up slowly until midlife and finally rises rapidly at the older ages. Table 2.1 shows differential mortality among age groups for males and for females over the past 16 years. To minimize the yearly fluctuations in the rates, the average sex-age-specific death rates for 1961–65 and 1972–76 have been used for the comparison.

**Table 2.1(a) Age-specific death rates (male), 1961–1965 and 1972–1976\****Deaths per 1,000 male population*

Age group	1961–65	1972–76	% change
			1972–76/1961–65
0	35.3	17.8	-50
1–4	3.1	1.0	-67

60–64	15.0	12.3	-18
65–69	20.3	18.1	-11
70–74	36.6	28.9	-21
75 and over	81.3	70.2	-14

\*Revised rates based on revised population estimates after 1976 By-census.

This shows that the average age-specific death rates for the two 5-year periods are always higher for males than for females and that, while death rates have fallen for all ages, the greatest reduction has been in the younger age groups. It should also be noted that for almost all age groups between 0 and 45, the declines in female mortality have been more remarkable than those in male mortality; and vice versa for all ages above 45.

### 3 Changes in mortality by cause

Different causes of death affect both males and females in different age groups by different degree. The uneven rate of mortality decrease among the population in different sex-age groups over the past decades was probably largely associated with the change in the pattern of the major causes of deaths.

The pattern of the causes of death in Hong Kong changed considerably during the period 1961–76. Again, to minimize the yearly fluctuations, the deaths from all causes over a 5-year period have been used for the analysis. Table 3.1 gives the percentage distribution of all deaths by causes for 1961–65 and 1972–76.

**Table 3.1 Percentage distribution of deaths by cause of death, 1961–1965 and 1972–1976**

Cause of death	1961–65	1972–76	Increase/decrease
			(1972–76)–(1961–65)
Infectious and parasitic diseases	13.6%	5.3%	- 8.3%
Neoplasms	14.5	22.2	+7.7
Diseases of the circulatory system	21.3	26.4	+5.1
Diseases of the respiratory system	14.4	16.1	+1.7
Diseases of the digestive system	6.5	5.0	-1.5

<i>Cause of death</i>	1961-65	1972-76	<i>Increase/decrease (1972-76)-(1961-65)</i>
Congenital anomalies and causes of perinatal mortality	8.2%	4.2%	-4.0%
Ill-defined causes	17.1	16.2	-0.9
Accidents, poisonings and violence			
All other causes	4.4	4.6	+0.2
All causes	100.0	100.0	0.0

Deaths due to infectious and parasitic diseases that used to account for over 13% of the total deaths in the period 1961-65 dropped to about 5% in 1972-76. The decline in deaths from congenital anomalies and causes of perinatal mortality was also fairly significant. On the other hand, neoplasms that contributed less than 15% of the total deaths in 1961-65 increased markedly to over 22% in 1972-76. The increase in deaths from diseases of the circulatory system was also significant.

#### 4 Changes in standardized cause-specific death rates and their effects on trends in mortality by age

The change in the percentage distribution of all deaths by cause shows changes in the relative importance among the various cause groups over time. They cannot, however, show changes in the magnitude or the direction of the cause-specific mortality trend. For the latter purpose, it is necessary to compare the cause-specific death rates for the two periods. To eliminate the effect of the changing age structure of the population, the cause-specific death rates have been standardized based on the sex-age distribution of 1976. Table 4.1 gives the standardized cause-specific death rates for both sexes for the periods 1961-65 and 1972-76.

**Table 4.1 Standardized cause-specific death rates, 1961-1965 and 1972-1976**

<i>Cause of death</i>	<i>Deaths per 100,000 population</i>					
	<i>Male</i>			<i>Female</i>		
	1961-65	1972-76	% change 1972-76/ 1961-65	1961-65	1972-76	% change 1972-76/ 1961-65
Infectious and parasitic diseases	110.0	42.3	-62	52.2	13.7	-74
Neoplasms	122.9	136.4	+11	97.9	96.4	- 2
Diseases of the circulatory system	210.7	139.8	-34	180.1	141.2	-22
Diseases of the respiratory system	89.4	90.6	+ 1	86.8	80.0	- 8
Diseases of the digestive system	47.6	33.1	-31	29.0	19.0	-35
Congenital anomalies and Causes of perinatal mortality	28.4	22.2	-22	21.5	17.1	-20
Ill-defined causes	95.3	37.9	-60	108.7	51.6	-53
Accidents, poisoning and violence	54.1	53.8	- 1	30.9	29.1	- 6
All other causes	33.3	23.4	-30	28.5	25.1	-12
All causes	791.7	579.5	-27	635.6	473.2	-26

Over the past 16 years, the death rate from infectious and parasitic diseases dropped markedly by 62% for males and 74% for females. The decline in mortality from this group of diseases, which mainly affects the very young and the old, contributed significantly to the remarkable decline in infant mortality, especially post-neonatal mortality, during this period; and had a substantial effect on the decline in mortality at the older ages.

Mortality from diseases of the digestive system showed a significant decline over the period 1961-76, 31% for males and 35% for females. The improvement, however, was much more marked among infants and children under 15. The effect of the decline in mortality from this group of causes on the decline in infant mortality, especially post-neonatal mortality, was as significant as that of the decline in infectious and parasitic diseases.

Immaturity, birth injuries, and other causes of an endogenous nature associated with perinatal mortality continued to decrease over the period 1961-76. This resulted in a notable decline in neonatal mortality and thus contributed, but in a less degree, to the decline in infant mortality generally.

There was a notable increase in deaths from congenital anomalies, but the rate was still comparatively low.

Diseases of the circulatory system mainly affect the very old. The increase in the number of deaths from these diseases, and in their proportion of total deaths, was mainly the result of the rapid growth in the number of old people. Mortality from this group of diseases, as indicated by the standardized death rates, actually dropped by as much as 34% for males and 22% for females over the period 1961-76. This contributed significantly to the mortality decline among the population in the age groups 50 and over.

Mortality from diseases of the respiratory system showed a slight increase for males and a decrease for females during the period 1961-76. The rates fluctuated widely from year to year, but the fact that the change over time was minor could indicate that these fluctuations were random.

Neoplasms was the only cause group where a significant increase in the death rate was recorded over the period 1961–76; the increase in neoplasm deaths, however, was different for both sexes. Mortality from this group of diseases increased by as much as 11% for males, but for females a drop of less than 2% was recorded. The increase may be partly due to better diagnostic techniques developed recently for this group of diseases, although this is difficult to quantify.

With the improvement in diagnostic techniques, deaths classified under 'ill-defined' causes continued to decline markedly. During the period 1961–76, the rate dropped by as much as 60% for males and 53% for females.

Accidents, poisoning and violence accounted for many deaths among the population in the age group 5–34. Road accidents and drowning were the main killers. The death rate was higher for males than for females. Mortality from this group of causes, however, showed no significant change over the period 1961–76.

Following the general trend of mortality decline, the death rate from diseases of the nervous system, genito-urinary system, skin, musculo-skeletal system and those related to pregnancy, child-bearing and puerperium etc. continued to fall during the period 1961–76. The rate of decrease was relatively more significant for males than for females.

## **5 Future mortality trends by cause**

Mortality has been falling steadily since 1961. In view of the existing socio-economic conditions in Hong Kong and advances in medical technology, there is every reason to believe that the present trends in mortality in all sex-age groups will continue in the future, although the rate of decrease is likely to be slower and not of the same extent among different cause groups. A direct extrapolation of past trends in the age-specific death rates would, it is felt, result in an over-estimation of the decline in mortality, in particular, as the declines in mortality from different causes of death constitute different declines in mortality in different age groups. The projection of the age-specific death rates, therefore, involves the separate projection of the trends in mortality from different cause groups for males and for females. To eliminate the effect of changing age structure of the population, the standardized sex-cause-specific death rates have been used in the projection. It is believed that, discounting the age effect, mortality from each cause group would decrease (or increase) on the present trend at a more or less constant rate. A log-linear trend was therefore fitted to the time series of the standardized death rates for each group of causes of deaths in the past 16 years and projected to the next 20 years. The projected trends were modified at a later stage in the light of the experience of more advanced countries.

The second step in the projection involves the assessment of the impact of the change in mortality from different cause groups on the death rates for males and females in different ages. This is achieved by comparing the average sex-age-cause-specific death rates for the two 5-year periods 1961–65 and 1972–76. The assumptions about the future pattern of mortality from the various cause groups by age and sex have been based on information on the existing trends and the comparison of the conditions in Hong Kong with those in more advanced countries.

Mortality from infectious and parasitic diseases declined rapidly in the past 16 years. In the light of observation of the pattern of this group of diseases in other countries, it appears likely that the fairly rapid rate of decrease for males may persist over the next 20 years. For females, however, since the death rate is already very low, any future decline must be at a slower rate.

During the past years, the decline in mortality from this group of diseases was mainly concentrated in the younger ages, especially among infants and children under 15. In view of the fact that the death rate of this cause group for ages under 15 is already very low, any further decline in future years should be less significant. This should also apply to the decline in the death rate for the older ages.

Mortality from neoplasms increased steadily during the period 1961–76. The present death rate in this cause group is, however, still low compared with that in developed countries, and it appears likely that the upward trend in mortality from neoplasms would continue in the next 20 years. In spite of the projected increase in the death rate, advances in medical technology and improvements in diagnostic techniques would assist treatment in the young and middle ages. It is therefore assumed that over the period of the projection the increase in the death rate of neoplasms would be mainly in ages under 15 and over 55.

In spite of a notable increase in deaths from diseases of the circulatory system, the standardized death rate of this cause group actually dropped considerably over the past 16 years. The declining trends are in line with those observed in developed countries. Although the death rate of this cause of diseases has dropped to a level lower than that prevailing in these countries, it is believed that the present trends will continue in the future but at a slower rate of decrease. It is assumed in the projection that the rate of decrease in mortality from this cause group would be reduced to half of the level observed over the past 16 years.

Mortality from this cause group increases rapidly with age. It has little effect for ages under 15. It is therefore assumed that over the period of the projection the decline in the death rate of diseases of the circulatory system would be in ages 15 and above, and that the decline would be least significant among the very young and the old.

The death rate of diseases of the respiratory system fluctuated widely from year to year during the past 16 years. The trend values however remained more or less stable over the period. Mortality from this group of diseases is still fairly high compared with that in developed countries. On the other hand, the relatively high mortality from this cause group is in line with that observed in other sub-tropical countries whose experience seems more relevant than that of countries with colder climates. It is therefore assumed in the projection that

the death rate of these diseases would remain unchanged at the present level and that the mortality pattern by age would also not be affected.

Mortality from diseases of the digestive system has declined rapidly in the past decade. The decline was most significant in the younger ages 0–4. The present death rate of this cause group for males is still fairly high compared with that in developed countries and there seems to be room for further improvement. On the other hand, the rate has already reached at very low level for females. It is therefore assumed in the projection that the current trend in mortality from this cause group for males would continue in the future and that the trend for females would be declining at  $\frac{1}{3}$  of its original speed. The decline would continue to be more significant in the younger ages 0–4 and less significant in the older ages.

Mortality from congenital anomalies and causes of perinatal mortality decreased steadily in the past. With continuous improvements in the provision of maternal and child health facilities and advances in medical technology, it appears that the declining trend would continue in the future, although the rate of decrease would be reduced. The decline in the death rate would, of course, be mainly in the young age groups, especially under 1.

With rapid improvements in diagnostic techniques, the number of deaths classified as from ill-defined causes dropped markedly over the period 1961–76. The death rate for the older ages classified under this cause group, however, is still fairly high compared with that in developed countries and the declining trend observed in the past would most probably continue in the future. The decline should be concentrated mainly in ages 15 and above.

The death rate of accidents, poisoning and violence fluctuated widely from year to year. The trend values however remained more or less stable over the period 1961–76. It is therefore assumed in the projection that the death rate of this cause group would remain unchanged at the present level and that the mortality pattern by age would also not be affected.

Mortality from all other causes, which was proportionately low, continued to decline during the period 1961–76. It is assumed in the projection that the declining trend would continue in the future and that the decline would be relatively less significant towards the older ages.

## 6 Projected sex-age-specific death rates

In order to secure a more stable base for the projection of mortality, the average sex-age-cause-specific death rates for the 5-year period 1972–76 have been used. The projection is made separately for males and for females. The first step in the projection is to compute an index of increase (or decrease) for the death rate of each cause group for each successive future year (which is derived from comparing the projected standardized death rate of the particular cause group for the respective future year with that for the base period). The index of increase (or decrease) for any cause group is disaggregated by age, based on assumed differentials in the mortality increase (or decrease) in the different broad age groups, and applied to the corresponding age-cause-specific death rates for the base period. After repeating this process for all cause groups for the respective future year, the next step is to sum the projected age-cause-specific death rates to arrive at the projected age-specific death rates for that particular year.

The set of the projected sex-age-specific death rates is used in the medium projection. For the high projection, a 5% downward adjustment, and for the low projection a 5% upward adjustment is made based on the average deviation of the actual death rates from the trend values. Table 6.1 shows the projected sex-age-specific death rates for the years 1976, 1981, 1986, 1991 and 1996 for each of the three projections. A graphical illustration of the change in the death rates over time is given in Charts D1 and D2.

## BALANCE OF MIGRATION

### 1 Introduction

In Hong Kong, migration is an uncertain element in the growth of population. It is dependent on factors which are largely unpredictable and information is in any case incomplete. All that can be hoped for is a broad indication of past trends, with an assumption of continuity in the future. The overall movement of persons into and out of Hong Kong in a year (5 million either way) is, of itself, little use in this context, because the genuine migration component (as identified by those persons with a declared intention to reside in or leave Hong Kong for at least 1 year) is marginal in number and because an adequate breakdown of the overall number does not exist. For the purposes of the analysis, therefore, four components in the migrant streams are differentiated and dealt with separately, namely, emigrants; legal immigrants from China; legal immigrants from other countries; and illegal immigrants. Taken together these components constitute the total net balance of migration.

### 2 Emigrants

It is difficult to obtain specific information regarding the number of Hong Kong residents who emigrate. There is at present no real way of distinguishing between Hong Kong residents going abroad for visits and those emigrating by reference either to declared interest or subsequent decision. It is true that under the provisions of the Registration of Persons Ordinance any person who emigrates must surrender his identity card before departure, but many people do not do so. Fortunately, some information is now available from certain Consulates and Commissions on the number of immigrant and student visas issued to Hong Kong residents holding Hong Kong British Passports or Certificates of Identity. This data serves as a valuable check on the age-sex pattern of emigrants. However, because of incomplete coverage and the fact that some persons after obtaining a visa may change their minds about going or may return to Hong Kong after a short stay in these countries, it cannot represent the actual volume of emigration.

Crude estimates of the volume of emigration have, therefore, to be derived from the difference between total arrivals and departures of Hong Kong residents holding Hong Kong British Passports and Certificates of Identity. In the long run, any temporary movements (including persons going abroad for tourism) should be eliminated by this process, and the difference over time should provide an indication of the trend in emigration. Table 2.1 below shows the arrival and departure figures at the airport and harbour (travelling by ocean-going vessels) in relation to Hong Kong residents (Hong Kong British Passports and Certificates of Identity holders).

**Table 2.1 Arrivals and departures of Hong Kong residents holding Hong Kong British Passports and Certificates of Identity, 1964–1976**

<i>Year</i>	<i>Arrival</i>	<i>Departure</i>	<i>Balance</i>
1964	28,846	39,151	– 10,305
1965	29,765	40,327	– 10,562
1966	38,487	54,149	– 15,662
1967	55,814	76,627	– 20,813
1968	90,087	96,942	– 6,855
1969	114,439	125,492	– 11,053
1970	138,336	140,142	– 1,806
1971	128,985	140,481	– 11,496
1972	155,506	174,304	– 18,798
1973	247,816	280,980	– 33,164
1974	320,259	353,645	– 33,386
1975	357,046	398,908	– 41,862
1976	394,569	435,014	– 40,445
1964–1976	2,099,955	2,356,162	–256,207

It can be seen that the balance of arrivals and departures of Hong Kong residents was consistently negative throughout the period 1964–76. The larger outflow recorded in 1967 might have been associated with the local disturbances in the summer of 1967, with some degree of return resulting in the net outflow dropping considerably during the period 1968–70. Since 1971, the outflow has been on the rise, reaching a level of some 40,000 in the years 1975 and 1976. The total outflow for the whole period 1964–76 is estimated to have been of the order of 256,000, and for the latter half of the period (i.e. 1971–76) of the order of 179,000. In all the circumstances, the assumption is made that the net outflow in future years will fluctuate between 20,000–35,000.

### 3 Legal immigrants from China

During the period 1964–76, the number of legal immigrants from China totalled 183,881. Admissions were at a high level in 1964 and 1965, but gradually came down to a very low level by 1971. From the second half of 1972, the number increased significantly. It reached a peak of about 55,000 in the year 1973, but thereafter declined, a total of 18,000 being recorded in 1976. For the period mid-1971 to mid-1977, the average number

of entries in this category was around 26,000 each year; for the period mid-1974 to mid-1977, (i.e. after the 1973 peak) the figure was about 22,000. Recent figures indicate that it would be reasonable to centre the assumptions as to the number of entries at around this level.

Table 3.1 shows the number of immigrants entering Hong Kong via Lo Wu from China during the period 1964–76.

**Table 3.1 Legal immigrants entering Hong Kong via Lo Wu from China, 1964–1976**

<i>Year</i>	<i>Number</i>
1964	13,055
1965	8,554
1966	5,209
1967	1,761
1968	2,159
1969	597
1970	446
1971	2,486
1972	20,588
1973	55,243
1974	32,018
1975	23,755
1976	18,010
1964–1976	183,881

#### 4 Legal immigrants from other countries

With the existing data collection system, there is no specific information regarding the number of immigrants from other countries. The records maintained by the Immigration Department merely show the number of entry permits and visa applications approved but the number of immigrants is probably in fact less than this, since some immigrants may fail to come after obtaining an entry permit or visa and some may leave Hong Kong after staying for a short period or at the termination of their employment contracts.

There is another source of data in relation to immigration from other countries. A register of British and Commonwealth citizens residing in Hong Kong and a register of non-Commonwealth alien residents, i.e. citizens of non-Commonwealth countries who were granted temporary or permanent residential status to enable them to stay in Hong Kong for a period of 6 months or more are maintained by the Immigration Department. From these registers, it is possible to obtain the number of alien residents and British and Commonwealth citizens residing in Hong Kong at the end of each year. An estimate of the number of immigrants from these countries can be derived by taking the difference between each annual period, although it will be affected by temporary movements and by any time lag between arrival and registration due to administrative procedures. The number of resident aliens and British and Commonwealth citizens at each end-year from 1973 to 1976 are shown in Table 4.1 below.

**Table 4.1 Number of resident aliens and British and Commonwealth citizens, 1973–1976**

<i>Year</i>	<i>Resident aliens</i>	<i>British/Common- wealth citizens</i>	<i>Total</i>	<i>Net gain from preceding year</i>
End-1973	26,825	31,574	58,399	—
End-1974	25,894	37,938	63,832	5,433
End-1975	26,316	42,960	69,276	5,444
End-1976	29,886	47,450	77,336	8,060
1974–1976	—	—	—	18,937

It can be seen that during the period 1974–76, an increase in the number of alien residents and British and Commonwealth citizens residing in Hong Kong was of the order of 19,000, or an average of some 6,500 annually. For the purposes of the projection, it is assumed that an annual net increase would be of the order of 7,000.

#### 5 Illegal immigrants

Statistics on the number of illegal immigrants entering Hong Kong are incomplete and difficult to obtain. Such data is only available when illegal immigrants turn up for registration for identity cards. Some illegal immigrants would register soon after arrival and some register after a longer period.

An estimate of the actual number of illegal immigrants entering Hong Kong each month who would subsequently turn up for registration within 12 months is made based on the relationship between the number of police arrests in that particular month and registrations within 12 months of arrival.

An estimate of the number of illegal immigrants who would register after 12 months of arrival (within 48 months) has been based on the average late registration pattern observed in the past. This estimate is imperfect

because it does not take into account those illegal immigrants who would register after 48 months. From a comparison between the overall results of the 1976 By-census and the current estimate of the population, it is possible to deduce that about 60% of illegal immigrants register within 12 months of arrival, with the remaining 40% of them registering after 12 months. This indication is used in revising the estimate of illegal immigrants over the years.

During the period 1964–70, the estimate of the number of illegal immigrants was around 10,000 a year; then it started increasing fairly rapidly, and was close to 30,000 in the year 1974. In 1975–76, the numbers (as estimated) decreased substantially. For the period mid-1976 to mid-1977, the estimate was of the order of 10,000.

## 6 Future migration trends – summary

Table 6.1 shows the assumptions concerning gross migration movements for each migration component for the three projections.

**Table 6.1 Migration assumptions by component and projected net balance of migration**

<i>Component</i>	<i>High projection</i>	<i>Medium projection</i>	<i>Low projection</i>
Emigrants	–20,000	–30,000	–35,000
Legal immigrants from China	26,000	22,000	18,000
Legal immigrants from other countries	7,000	7,000	7,000
Illegal immigrants (including overstayers)	15,000	13,000	10,000
Net balance of migration	28,000	12,000	nil

## METHODS OF COMPUTATION

### 1 Introduction

To make a population projection, it is necessary to establish first accurate data on the age and sex structure of the population at a point in time to form the base for the projection. The base population in each sex-age group is then projected for future years based on the projected future number of births and deaths and the balance of migration.

### 2 Base population

The base population for the present set of projections was obtained from the 1976 By-census. The By-census consisted of two separate operations: the marine census and the land census. The former was conducted in May and the latter in August. In the first place, it was necessary to bring these two enumerated populations to the same reference date. The enumerated marine population was therefore adjusted from the marine census moment of 30 May 1976 to the land census moment of 2 August 1976 by 'aging' the population for 64 days and by adding births and subtracting deaths by age which occurred during the 64-day period. Migration amongst the marine population was taken to be nil. The enumerated land population and the adjusted marine population were then added together to form the total population as at 2 August 1976.

This total population was then adjusted for error due to mis-statements of age. In this calculation the population figures were first arranged in quinquennial age groups 6–10, 11–15, 16–20 etc. This set of groupings was found to give the least age-reporting error. From the grouped data, graduated values of population at single years of age were obtained by osculatory interpolation using Sprague's multipliers.

The graduated values were then adjusted for under-enumeration on the basis of the land post-enumeration check. For the young ages 0–5, known birth figures for the period August 1972–July 1976 from the Registrar General's Department were used as control to guard against under-enumeration of infants and children under 5 which was found to be relatively more severe as compared with that in the older ages.

The total population after these adjustments was brought forward to mid-year 1976. This was achieved by backward 'aging' the population by 33 days from 2 August to 30 June 1976, and by subtracting births and adding deaths by age which occurred during the 33-day period. Population increase brought about by the net balance of migration over the period was also deducted. The resultant of these adjustments was the estimated population at mid-year 1976, the base population for the projection.

### 3 Births

On the basis of the analysis of the past and current fertility data, a set of assumptions was made about future fertility trends upon which the age-specific fertility rates were projected for each of the three projections, i.e. high, medium and low. The projected number of births for an annual period was obtained by applying the projected age-specific fertility rates to the average number of women in each of the child-bearing ages in the year and summing the results over the reproductive ages of 15–49. The projected number of births for each annual period after allowing for infant deaths would form the population under 1 at the end of the projected annual period.

Since separate projections were to be prepared for males and for females, it was necessary to project the number of male and female births. In the projection of fertility, the age-specific fertility rates referred to births of both sexes combined; the number of male and female births were estimated by reference to an average sex-ratio at birth using known birth data for the years 1970 to 1976 as shown in Table 3.1 below.

Table 3.1 Known births by sex, 1970–1976

<i>Year</i>	<i>Male</i>	<i>Female</i>
1970	39,608	36,983
1971	41,095	38,692
1972	41,472	38 865
1973	42,282	39,708
1974	42,966	40,613
1975	41,519	38,240
1976	40,775	37,727
1970–1976	289,717	270,828

$$\begin{aligned}\text{Average sex-ratio at birth for 1970–1976} &= \frac{289,717}{270,828} \times 1,000 \\ &= 1,070\end{aligned}$$

### 4 Survivorship

Based on the assumptions concerning future mortality trends, three sets of sex-age-specific death rates were projected for the high, medium and low projections. The projected sex-age-specific death rates were converted

into  $q_x$  (the probability of dying between exact age  $x$  and exact age  $x+1$ ). The life table functions  $l_x$  (survivors of the life table cohort at exact age  $x$ ) and  $L_x$  (number of years lived by the life table cohort from exact age  $x$  to exact age  $x+1$ ) were then computed, and from these the survival ratios ( $L_{x+1}/L_x$ ) were formed.

The population of each sex at a particular age  $x$  at the beginning of the projected annual period (year  $t$ ), after allowing for deaths during the period by applying the survivorship rate to the population, will become the population at age  $x+1$  at the end of the projected annual period (year  $t+1$ ). In notation form, this could be represented as follows:

$$P_{x(t)} \cdot S_{(x, x+1) (t, t+1)} = P_{(x+1) (t+1)}$$

where  $P_{x(t)}$  = number of persons at any age  $x$  at the beginning of the projected annual period (year  $t$ )

$S_{(x, x+1) (t, t+1)}$  = Survival ratio of the population from age  $x$  in year  $t$  to age  $x+1$  in year  $t+1$

$P_{(x+1) (t+1)}$  = number of persons aged  $x+1$  at the end of the projected annual period (year  $t+1$ )

The survival ratio at birth ( $L_0/l_0$ ) was calculated and applied to the projected number of births for the projected annual period to give the numbers surviving at age under 1 at the end of the period.

Details concerning the construction of the life table are given in a separate publication in this series entitled 'Hong Kong Life Tables'.

#### 4 Migration

To simplify the computation process for the projection, it was assumed that the net balance of migration over a projected annual period would be concentrated on the last day of the period. In this way, it was not necessary to take account of the births and deaths among migrants during the projected annual period. The net balance of migration was added to the projected population at the end of the projected annual period (year  $t$ ) which formed the population at the beginning of the next projected annual period (year  $t+1$ ). The immigrants were then subject to the same projected birth rates and survival ratios for subsequent periods as those assumed for the Hong Kong population as a whole.

These assumptions are fairly crude, but without accurate knowledge of the fertility behaviour and survivorship pattern of the immigrants they are the best that could be made.

Each of the four components of migration – emigrants, legal immigrants from China, legal immigrants from other countries, and illegal immigrants including overstayers – has its own age and sex structure and different levels assumed for the high, medium and low projections. The age and sex distribution of the projected net balance of migration for each of the three projections was estimated by summing the average sex-age distribution of each of the components, which in turn was derived from the administrative records available in recent years. Before summation, the average sex-age distribution of each migration component was weighted by the numbers assumed for the high, medium and low projections.

# Definitions

## DEFINITIONS

### **Age-cause-specific death rate**

The ratio of the number of deaths (for each sex) in each age group from each group of diseases occurring during a calendar year to the total population (for each sex) in that age group at the middle of that year.

### **Age-specific birth rate by birth order**

The ratio of the number of live births of each birth order occurring to mothers in each child-bearing age group during a calendar year to the total female population in that age group at the middle of that year.

### **Age-specific death rate**

The ratio of the number of deaths (for each sex) in each age group occurring during a calendar year to the total population (for each sex) in that age group at the middle of that year.

### **Age-specific fertility rate**

The ratio of the total number of live births occurring to mothers in each child-bearing age group during a calendar year to the total female population in that age group at the middle of that year.

### **Birth order (birth parity)**

The number of births to a mother.

### **Cause-specific death rate**

The ratio of the number of deaths (for each sex) from each group of diseases occurring during a calendar year to the total population (for each sex) at the middle of that year.

### **Cohort**

A group of persons all born during the same year being analysed as a unit through their lifetime.

### **Birth rate**

The ratio of the total number of live births occurring during a calendar year to the total population at the middle of that year. The birth rate calculated on this basis is described as the 'crude birth rate' since it is averaged over the population at large and disguises what can be quite significant differences between the various ages.

### **Death rate**

The ratio of the total number of deaths occurring during a calendar year to the total population at the middle of that year. The death rate calculated on this basis is described as the 'crude death rate' since it is averaged over the population at large and disguises what can be quite significant differences between the various ages and the sexes.

### **Log-linear trend**

A trend (fitted by the method of least squares) of time series plotted against a logarithmic Y-scale.

### **Net reproduction rate**

The total number of female children that would be born per woman to a cohort of women as they pass through the child-bearing ages 15–49, allowing for mortality of some of the women up to and during this period, according to constant fertility and mortality conditions.

### **Standardized death rate**

The ratio of the number of 'expected' deaths during a calendar year to a standard population. The number of deaths was derived by applying the age-specific death rates for that year to the age and sex distribution of the standard population. The standardized death rate is not influenced by age and sex structure since it is based on a fixed population.

### **Survival ratio**

The proportion of survivors in a cohort at any particular age, derived from the specific life table based on the assumed schedule of death rates.
